Movement, activity and action: the role of knowledge in the perception of motion

AARON F. BOBICK

MIT Media Laboratory, 20 Ames Street, Cambridge, MA 02139, USA (bobick@media.mit.edu)

SUMMARY

This paper presents several approaches to the machine perception of motion and discusses the role and levels of knowledge in each. In particular, different techniques of motion understanding as focusing on one of movement, activity or action are described. *Movements* are the most atomic primitives, requiring no contextual or sequence knowledge to be recognized; movement is often addressed using either view-invariant or view-specific geometric techniques. *Activity* refers to sequences of movements or states, where the only real knowledge required is the statistics of the sequence; much of the recent work in gesture understanding falls within this category of motion perception. Finally, *actions* are larger-scale events, which typically include interaction with the environment and causal relationships; action understanding straddles the grey division between perception and cognition, computer vision and artificial intelligence. These levels are illustrated with examples drawn mostly from the group's work in understanding motion in video imagery. It is argued that the utility of such a division is that it makes explicit the representational competencies and manipulations necessary for perception.

1. INTRODUCTION

Recently, there has been a shift in computer vision from the processing of static images to the consideration of video sequences. The majority of previous work on sequences of images has focused on recovering the geometry of the scene—*structure from motion*, the camera motion—*egomotion*, or the motion of the pixels themselves—*optic flow* (Cedras & Shah 1994). Current research, however, has begun to investigate the recognition of the action taking place in the scene. The fundamental question being addressed is no longer 'how are things moving?' but 'what is happening?' (Bobick 1996).

However, there has been much confusion about exactly which interpretation problems constitute understanding action. For example, Polana & Nelson (1994) and Shavit & Jepson (1993) focus on direct motion properties of the image pixels to detect activities such as walking or running. There is no knowledge about time, sequence, or causality embedded in the interpretation process. The 'action' is coded strictly in the statistics of image motion. Jumping, for example, has a particular signature in a local spatiotemporal region of the image sequence.

In sharp contrast is work such as that by Siskind (1995) and Mann *et al.* (1996). In these approaches the interpretation of the motion of objects is accomplished by analysing the action in terms of a qualitative physics description. Mann's system understands that the proposition of an attachment to an active—self-propelled—moving object is adequate to explain the movement of a passive entity. In these systems, understanding action implies producing a semantically rich description that includes primitives such as 'pick-up' or 'bounce'. To produce such descriptions requires a representation of the causal relations in qualitative physics; often an extended representation of time, as opposed to an instantaneous or signal-based view, is needed as well.

The goal of this paper is to analyse various approaches to understanding motion with respect to the nature and amount of the knowledge required. Drawing mostly from examples of our own work, I will propose three levels of motion-understanding problems labelled, in increasing order of knowledge implied, as movement, activity and action. The advantage of considering motion interpretation problems this way is that upon presentation of an algorithm or application task one can immediately compare the work to other approaches, and in particular consider the competence of the representation and knowledge employed.

Before continuing, it is necessary to note the pioneering work of Hans Nagel in the general area of machine perception of motion (Nagel 1977), and in the specific endeavor of attempting to characterize motion understanding problems (Nagel 1988). His taxonomy of 'change, event, verb, episode, history' reflects different dimensions of the problem than those discussed here, but it does provide an interesting alternative view. The 1988 paper begins with the sentence: 'Today, the design of a program which "understands" image sequences appears an ambitious but not totally unrealistic research goal.' It still feels ambitious.

2. PERCEPTION OF MOTION: MOVEMENT, ACTIVITY AND ACTION

Suppose we wish to construct a system that recognizes different motions in a particular application domain: a baseball game. Let us consider three distinct 'actions' one might want to identify: swinging the bat, pitching the ball and tagging out a runner. In this section we will argue that these three tasks are illustrative of three classes of motion-understanding problems and that the techniques necessary to recognize them will differ in the type of knowledge required and how that knowledge is applied.

If one observes numerous players swinging a bat one would see little variation in the motion. While the exact stance and configuration of the static bat prior to the swing may vary, the motion itself is predictably similar from one instance to the next. We say 'predictably' because the physical dynamics of the task—accelerating a stick to a speed sufficient to propel the ball (hopefully) 450 feet—and the kinematics of the human actuator constrain the motion to be performed in a particular manner.

We term this type of motion a *movement*—a motion whose execution is consistent and easily characterized by a definite space–time trajectory in some configuration space (in this case the kinematics of the human body). For a given *viewing condition* execution consistency implies consistency of appearance: the appearance of the motion can be described reliably in terms of the motion of the pixels. The pixel-based description of the motion under different viewing conditions is the only knowledge required to see the movement.

Approaches to the perception of movements include the previously mentioned work by Polana & Nelson (1994) and Shavit & Jepson (1993). These techniques are based on periodicity measurements of the pixels or blobs undergoing motion. In §3 we will describe two techniques developed in our laboratory for recognizing human movements.

Pitching a baseball involves many more steps than hitting. Typically, but not always, a pitch involves (i) bringing the arms together in front of the body to achieve balance on two feet; (ii) swinging the arms back; (iii) kicking the front leg up while leaning back; (iv) delivering the pitch. (Apologies to connoisseurs of the game; the descriptions here are simplified approximations.) Some instances diminish the effort or reduce the time put into one phase or another, or may even eliminate a stage entirely. The motion is no longer a single, primitive, consistent movement. Rather, it is an *activity*: a statistical sequence of movements. Recognition of such a motion requires knowledge about both the appearance of each constituent movement and the statistical properties of the temporal sequence.

An important domain area that requires addressing activity is that of recognizing gait. Rohr (1994) and Niyogi & Adelson (1994) make an explicit model of the sequence of movements or configurations that form the activity of walking. In both of these approaches the sequence is fixed and deterministic. The work by Black

& Yacoob (1995) on understanding facial expression coded a qualitative variation over time of the shape of face features.

The recent surge in interest in hidden Markov models (HMMs) to process video sequences reflects the goal of explicitly representing statistical sequential information. One of the earlier efforts is by Starner & Pentland (1995) where HMMs are used to understand American sign language (ASL); the success HMMs have attained in the speech community was a strong motivation to apply them to the analogous ASL task. In section 4 we will describe some recent work in our laboratory that focuses on how activities may not be represented easily by a single feature set; as the activity progresses the underlying representation may need to vary.

Finally, what does it take to see a runner being tagged out? Semantically, the description is straightforward: a fielder with the ball causes his glove to come in contact with a base-runner who is not touching a base at the time. Visually, however, the appearance is difficult to define or describe due to the variability of how the movements may be made. The motion to be recognized needs to be understood in a context: the best explanation of the sequence of movements is that the fielder is intending to tag the runner which is why he is moving his arm down while the runner is trying to get to the nearest base. Tagging a runner is an *action* which we define to include semantic primitives relating to the context of the motion. For a system to recognize actions it must include a rich knowledge base about the domain and be able to hypothesize and evaluate possible semantic descriptions of the observed motion.

As defined, actions are at the boundary of where perception meets cognition. Indeed, researchers proposing formal theories of semantics and inference of action (Schank 1975; Jackendorf 1990; Israel *et al.* 1991) address motion at this level of analysis. Being primarily focused on computer vision my goal is to stay as connected to the visual signal as possible, where predefined actions (e.g. 'tagging out a runner' or 'mixing ingredients') and particular semantic labels (e.g. 'base-runner' or 'chef') have direct visual correlates. Mann *et al.* (1996) accomplish this by postulating that certain behaviours suggest particular causal relationships, and that those relationships have visual consequences that can be verified. In §5 we briefly outline a system we have developed that uses logical descriptions of actions to deduce visual correlates; these correlates are then used to control the selection of vision routines.

In the following three sections we describe some results in computer vision—mostly from our laboratory—that reflect the levels described here. Our main goal is to focus on the knowledge and the representation of time employed by each set of techniques. At the conclusion of the paper we will discuss the utility of the taxonomy of the motion-understanding problems presented.

3. RECOGNITION OF MOVEMENT

Two recent efforts in our research group have focused on the direct recognition of movement. The first case, which we mention only briefly, is work on the recognition of ballet steps (Campbell & Bobick 1995). The
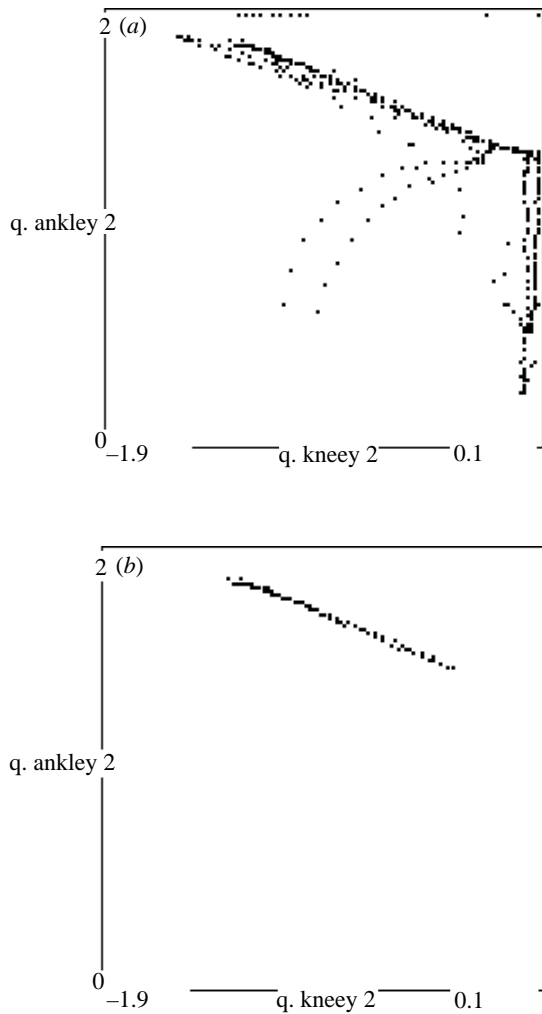

Figure 1. Two variable phase plots (ankle angle versus knee angle) for (*a*) a wide variety of ballet moves, and (*b*) points during plié moves. The simple curve in the second plot represents a detectable constraint in force during the execution of a plié.

approach we develop is based on the idea that different categorical movements, e.g. plié or relevé, each embody a different set of constraints on the motion of the body parts. These constraints are most easily observed in a phase-space that relates the independent variables of the body motion. This work presumes that the underlying three-dimensional kinematics of the body are recovered from video (e.g. using a method such as that of Gavrilla & Davis (1996)). Our question is not how to recover the three-dimensional structure; rather, given that structure, how do you see a plié?

Figure 1 illustrates an example. The phase plot in graph (*a*) displays the relation between the ankle angle and the knee angle of one leg of a dancer performing a wide variety of ballet steps. Graph (*b*) contains only those points recorded during plié steps. Because the tight constraint in (*b*) is not generally in force during other moves, detecting the presence of this relationship indicates the possibility of a plié being performed. By automatically learning from training data which sets of constraints are highly diagnostic of particular motions, we can build constraint set detectors to recognize the movements. Note that this technique is only applicable to the recognition of atomic movements; in this approach sequences of steps can only be recognized if each individual movement is detected.

A more generic movement recognition method is embodied in our recent work on *temporal templates* which aims for the direct recognition of movement from the motion in the imagery. Consider an extremely blurred sequence of action; a few frames of one such example are shown in figure 2. Even with almost no structure present in each frame, people can trivially recognize the movement as someone sitting when the frames are displayed as a video sequence. Such capabilities argue for recognizing action from the motion itself, as opposed to first reconstructing a three-dimensional model of a person, and then recognizing the action of the model. (Example sequences are available on the Web at http://vismod/www.media.mit.edu/vismod/archive.)

In Bobick & Davis (1996*a*,*b*) and Davis & Bobick (1997) we propose a view-based representation and recognition theory that decomposes motion-based recognition into first describing *where* there is motion (the spatial pattern) and then describing *how* the motion is moving. The basic idea is that we project the temporal pattern of motion into a single, image-based representation—a *temporal template*.

Figure 2. Selected frames from video of someone performing an action. Even with almost no structure present in each frame people can trivially recognize the action as someone sitting.

(a)

(b)

0°   20°   40°

50°   70°   90°

Figure 3. Example of someone sitting. (a) Top row contains key frames; bottom row is cumulative motion images starting from Frame 0. (b) MEIs for each of six viewing directions; the smooth change implies only a coarse sampling of viewing direction is necessary to recognize the action from all angles.

The top row of figure 3a contains key frames of a sitting sequence. The bottom row displays cumulative binary motion images—to be described momentarily—computed from the start frame to the corresponding frame above. As expected, the sequence sweeps out a particular region of the image; our claim is that the shape of that region can be used to suggest both the movement occurring and the viewing condition, in this case the horizontal viewing angle.

We refer to these binary cumulative motion images as *motion-energy* images (MEIs). Let $I(x,y,t)$ be an image sequence and let $D(x,y,t)$ be a binary image sequence indicating regions of motion; for many applications image-differencing is adequate to generate D. Then the MEI $E_\tau(x,y,t)$ is defined as

$$E_\tau(x,y,t) = \bigcup_{i=0}^{\tau-1} D(x,y,t-i).$$

We note that the duration τ is critical in defining the temporal extent of an action. During training, we need to define τ explicitly. Fortunately, to perform real-time recognition we can exploit a backward-looking (in time) algorithm that can dynamically search over a range of τ, yielding linear speed invariance in recognition.

In figure 3b we display the MEIs of sitting viewed over 90°. In Bobick & Davis (1996a), we exploited the smooth variation of motion over angle to compress the entire view circle into a low-order representation. Here we simply note that because of the slow variation across angle, we only need to sample the view sphere coarsely to recognize all directions.

To represent *how* motion is moving we enhance the MEI to form a *motion-history* image (MHI). In an MHI, pixel intensity is a function of the motion history at that point. For the results presented here we use a simple replacement and decay operator:

$$H_\tau(x,y,t) = \begin{cases} \tau \text{ if } D(x,y,t) = 1 \\ \max(0, H(x,y,t-1) - 1) \\ \text{otherwise} \end{cases}$$

The result is a scalar-valued image where more recently moving pixels are brighter. Examples of MHIs are presented in figure 4. Note that unlike MEIs, the MHIs are sensitive to direction of motion. Also note that the MHI can be generated by thresholding the MEI above zero. The MEI and MHI together form a temporal template of movement to be matched against unknown input motions.

To construct a recognition system, we need to define a matching algorithm for the MEI and the MHI. In Bobick & Davis (1996b) and Davis & Bobick (1997), we developed and tested a scale and translation invariant technique based upon statistical descriptions of the MEI and MHI images. We first collected training examples of each action from a variety of viewing angles. For each view of each movement a statistical model (mean and covariance matrix) is generated for shape moment parameters of both the MEI and MHI. The computation of the shape moments includes weighting by pixel intensities, giving different moments for the MEI and MHI. To recognize an input motion, a Mahalanobis distance is calculated between a shape moment description of the input and each of the known movements.

We have implemented a causal segmentation and recognition system that uses a backward-looking variable time window to achieve speed invariance. The

simple nature of the replacement operator allows the construction of a highly efficient algorithm capable of real-time operation on a standard Unix workstation. For example, one implementation runs at approximately 13 Hz using a colour CCD camera connected to a Silicon Graphics Indy. The images are digitized to a size of 160×120 covering movements of duration from one to two seconds. The matching operation is virtually no cost once the input image statistics have been computed; adding more classes of movement does not affect the speed of the algorithm, only the accuracy of the recognition.

In summary, the temporal templates are a method for recognizing movements, matching motion patterns between input and known models. The only statistics maintained are the variability of appearance from one instance to the next. Time is handled implicitly by developing a matching method that is insensitive to linear scaling with respect to time, i.e. a simple change of speed. Furthermore, there is no consideration of sequence. In fact, overly complicated movements that overwrite themselves often (self-occulusion in space–time) therefore give rise to temporal templates that are unreliable for matching. To recognize a series of atomic motions requires a more powerful representation of time and of the statistics of the temporal pattern.

4. RECOGNITION OF ACTIVITY: GESTURE IN COMMUNICATION

As defined, activities involve a sequence. The components of the sequence can either be movements or static states. If it is explicitly based upon states, then the sequence is implicitly defined by the movements that are required to move from one state to the next.

The representation of the sequence defining an activity can either be explicit and deterministic, or implicit and statistical. An example of the former case is that of Rohr (1994) where the positions of silhouette edges of a walking person are encoded as a one degree of freedom function of the phase of the gait. These edges are matched against those of a person in each input image of a sequence. The gait phase 'angle' is then estimated at each time instant yielding a description of the complete sequence in terms of a trajectory through the gait phases.

Examples of implicit and statistical representation of sequences are seen in the recent work on understanding human gesture (e.g. Starner & Pentland 1995; Wilson & Bobick 1995). Inspired by the succcessful application of hidden Markov models to speech recognition tasks, these methods represent activities—gestures—by probabilistic states where both the observed output of a given state and the transitions made between states are controlled by underlying probability distributions (Rabiner & Huang 1993). In the remainder of this section we will discuss the work in Wilson & Bobick (1995) because it not only maintains a Markovian model of the statistics of motion, but also learns the variation in representation of the imagery required to span the entire activity.

Two observations motivated the approach. First, human gestures are embedded within communication. As such, the gesturer typically orients the movements towards the recipient of the gesture (Darrell & Pentland 1993). Second, in the space of motions permitted by the degrees of freedom of the human body, there is a small subspace of that we use in the making of a gesture. Taken together, these observation argue for a view-based approach in which only a small subspace of human motions is represented.

How should a system model human motion to capture the constraints present in the gestures? There may be no single set of features that makes explicit the relationships that hold for a given gesture. In the case of hand gestures, for example, the spatial configuration of the hand may be important (as in a point gesture, when the observer must notice a particular pose of the hand), or alternatively, the gross motion of the hand may be important (as in a friendly wave across the quad). Quek (1993) has observed that it is rare for both the pose and the position of the hand to change simultaneously in a meaningful way during a gesture.

We first presented an approach that represents gesture as a sequence of states in a particular observation space (Bobick & Wilson 1995). We then extended that work and developed a technique for learning visual behaviours that (i) incorporates the notion of multiple models—multiple ways of describing a set of sensor data; (ii) makes explicit the idea that a given phase of a gesture is constrained to be within some small subspace of possible human motions; and (iii) represents time as a probabilistic trajectory through states (Wilson & Bobick 1995). The basic idea is that different models are needed to approximate the (small) subspace associated with each
Figure 5. A wave gesture. The recovered Markov model for all training sequences on the left shows the symmetry of the gesture. The mean image for each state is shown in the middle. On the right is a plot of membership (solid line) and residual (dotted line) for each state for one training sequence. The exact shape of the plots varies in response to the variance and length of the sequence.

particular state and membership in a state is determined by how well the state models can represent the current observation. The parsing of the entire gesture is accomplished by finding a likely sequence of states given the memberships and the learned transition probabilities between the states.

The details of the techniques are presented in Wilson & Bobick (1995). The approach is based upon state models that define a *residual*—how well a given model can represent the current sensor input. We then embed this residual-based technique within an HMM framework; the HMMs represent the temporal aspect of the gestures in a probabilistic manner and provide an implicit form of dynamic time warping for the recognition of gesture.

Here we illustrate the technique by way of two examples. Figure 5—a wave gesture—consists of a single model example but shows the use of the HMM. The model in use is a principal component decomposition of the input image. The parameters describing each image are the coefficients of projecting the input image onto a basis set of images, where there is a different set for each state of the HMM. The basis set for a state consists of the most significant eigenvectors of the set of images determined to belong that state. The residual between the input image and the best reconstruction using the basis set of a state determines the likelihood that the given state could generate the input image. Because the basis set determines state membership but state membership is used to select the basis set, the entire estimation process is an iterative expectation–maximization algorithm; we add the basis set selection step to the traditional Baum–Welch technique of HMM parameter estimation (Rabiner & Huang 1993). The different basis sets are the varying representation of the activity to which we referred earlier.

In the first example, the input data consist of 32 image sequences of a waving hand, each about 25 frames $(60 \times 80$ pixels, grey-scale) in length. The recovered Markov model, the mean image at each state, and plots of the memberships and residual for one sequence are shown in figure 5. The recovered Markov model allows the symmetry of motion seen in the plot of membership over an observation sequence. Some of the observation sequences differ in the extent of the wave motion; in these cases the state representing the hand at its lowest or highest position in the frame may not be used. For a new instance of a wave gesture to be recognized, a high probability parse using the HMM must be possible.

Our second example describes the position and configuration of a waving, pointing hand (figure 6). In each frame of the training sequences, a 50×50 pixel image window of the hand was tracked and clipped from a larger image with a cluttered background. Fore-
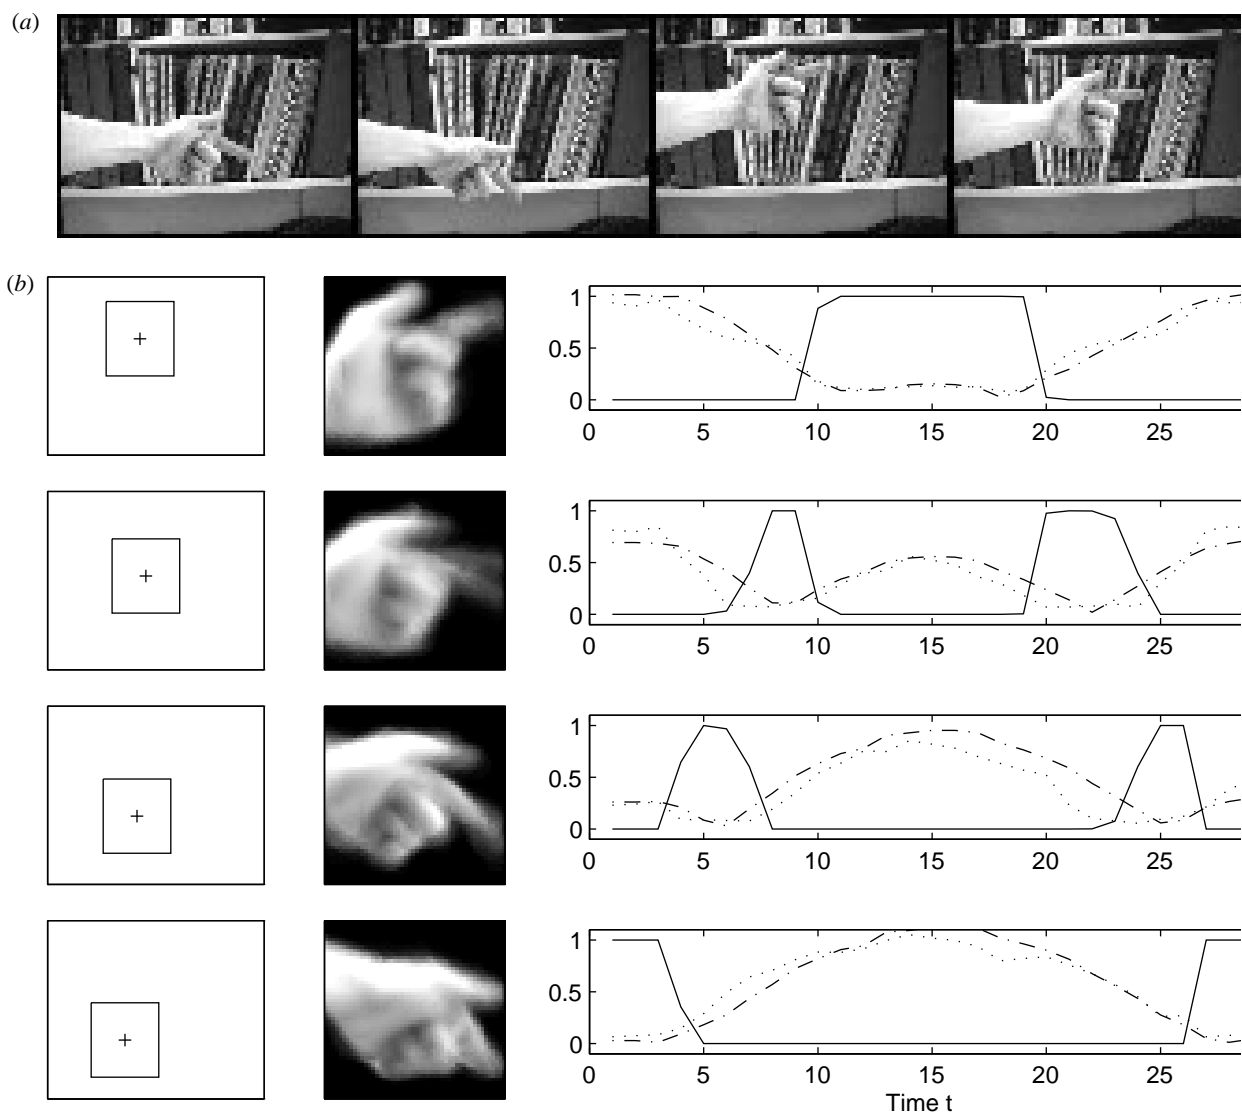

Figure 6. (*a*) Four representative frames (ordered left to right) are shown from one training sequence. (*b*) The mean location of the tracked band in the larger image is shown on the left. The mean image for each state is shown in the middle. On the right is a plot of membership (solid line), configuration residual (dotted line), and the position residual (dash–dot line) for each state for one training sequence.

ground segmentation was accomplished using the known background. The configuration of the hand is modelled by the eigenvector decomposition of the image windows. The position of the hand is modelled by the location of the tracked hand within the larger image. The recovered Markov model is similar to that of the waving hand in the previous example except now there are two components of the model of each state. As before, this gesture is recognized if a highly probable parse can be generated by the HMM.

The variance of each feature indicates the importance of the feature in describing the gesture. In this example both the position and configuration of the hand was relevant in describing the gesture. Had the location of the hand varied greatly in the training set, the high variance of the position representation would have indicated that that position was not important in describing the gesture. The important point here is that

each state defines the important models associated with that phase of the gesture.

The use of HMMs to encode the statistical sequence of movements or states associated with an activity has both advantages and disadvantages. The most important positive aspect of HMMs is their ability to learn the necessary states and transitions from training examples. Instead of a programmer explicitly coding the component movements or configurations, the learning algorithm will decompose the activity into natural phases. However, the disadvantage of HMMs is exactly the lack of control one has over the states recovered. Even if one has some *a priori* knowledge about the natural segments of an activity, it is difficult to incorporate them into the framework. Usually one can only affect the computation by specifying the topology of the state transition network to be learned.

An alternative to HMMs for the recovery of natural gesture was recently proposed in Wilson *et al.* (1996). In this approach, a fixed, non-deterministic, finite-state machine representation of the gesture sequence is employed. Each state is given a description in terms of the temporal properties of gesture. One such state would be described as being (i) similar in appearance to a 'rest' state of the gesturer, (ii) undergoing little motion, and (iii) in this state for a long duration. In this system only the duration parameters were learned from training data. The state transitions and descriptions were based on *a priori* understanding of the components of a sequence that make up the activity, in this case natural gesticulations. We demonstrated the ability to pick out semantically meaningful gestures comparable to an expert human observer.

Whether using HMMs or some other representation of activity, the requirements for recognition are the same: (1) a statistical or deterministic representation of a sequence of components that comprise the activity, and (2) a parsing mechanism that can temporally align the input signal with the known activity patterns. The knowledge encoded in these systems can be similarly considered as consisting of two elements. The first is the appearance or properties of the signal at different phases of the activity. While the gesture examples presented above are defined by individual static components, the baseball pitching example illustrates how some or all of the components may be atomic movements. The second element knowledge is the specification of the quantitative temporal relationships between these components.

What is common between movements and activities is that neither refers to elements external to the actor performing them. That is, their occurrence can be 'perceived' in the absence of knowledge of context or of the actor's interaction with other entities in the scene. Thus, the knowledge required to perceive movements or activities may be considered strictly perceptual. In the next section, we discuss motion-understanding problems that are not so self-contained.

5. RECOGNITION OF ACTIONS: REASONING ABOUT SPACE AND TIME

The highest level of motion understanding is action recognition. Earlier we defined the action recognition task as requiring an interpretive context—a set of constraints on possible explanations for the observed motions. The discussion of the system of Mann *et al.* (1996) for describing moving objects considered the use of the constraints of physics and measures of simplicity to derive likely explanations. The physical knowledge is exploited by providing consistency requirements and preference relations that any such explanation should satisfy.

A different focus is taken by Pinhanez and Bobick (Bobick & Pinhanez 1997; Pinhanez & Bobick 1996). In that work knowledge and the interpretive context are exploited to link perceptual signals to underlying actions. The application domain is *SmartCams*—cameraman-less cameras—that respond to a director's requests while filming a cooking show. Such cameras

perform inverse video annotation: given some symbolic description ('close-up chef') the system needs to generate the correct image.

From the perspective of this paper, the most important aspect of that work is the availability of a *script* that describes the actions that are taking place. These actions—e.g. the chef is chopping the chicken—are described using a logical formulation that allows perceptual inferences to be drawn. For example, the fact that the chef is chopping the chicken results in the assertion that the hands are moving and that they are near the chopping board. These inferences have visual implications and are exploited to select appropriate visual routines to perform the camera framing tasks. (For more details and a demonstration see: `http//vismod.www.media.mit.edu/vismod/archive`, and search for SmartCams.)

Fundamental to high-level action recognition is an explicit representation of time. One of the weaknesses of the SmartCam system as reported was a lack of a temporal reasoning mechanism that could consider temporal relationships between intervals; actions were strictly linear sequences. Recently, (Pinhanez & Bobick 1997) we have introduced the PNF constraint mechanisms for temporal intervals that supports reasoning about time and the relationship between sensors and actions taking place at any given moment. To construct sophisticated action recognition mechanisms we need to be able to represent non-trivial temporal relationships such as partial ordering. The PNF formulation is a real-time parsing mechanism, based on Allen's temporal interval calculus, that is designed to address such problems.

For example, using PNF it is simple to represent the action of *picking-up-a-bowl* as first the bowl is on the table, then the hands move towards and grasp the bowl, and then the bowl is off the table. Given a collection of such definitions and sensors capable of detecting events such as *hands-touching-bowl* or *bowl-off-table* the system can reason about which actions may be taking place currently. Using the PNF language it is also easy to say that A cannot take place at the same time as B, but both must occur before C for some action to be considered as having taken place.

While the inferences supported by the system are not adequate to reason deeply about action (such as modelling any deep causality; Israel 1991), many simple actions become possible to see. By simple, we mean actions that have direct perceptual implications and can be recognized without extensive causal reasoning. Such reasoning is sometimes referred to as shallow (Jain & Binford 1991) in that no explanatory theory is present. This is in contrast to systems such as that of Mann *et al.* (1996) mentioned above, where a qualitative physics theory is used to generate explanation based descriptions.

Whether the reasoning is shallow or deep, the knowledge required to perceive actions touches more than just the actor itself. Contextual or causal relations play a critical role. From the perspective of knowledge-based vision, the perception of action is the most knowledge intensive form of motion understanding.

6. CONCLUSION: UNDERSTANDING MOTION

The problem of interpreting motion ('understanding action') has become a major thrust of computer vision research. Unlike object recognition, where generic classes were replaced with specific geometric models to make the problem tractable, the task of understanding actions will typically require representations of more than just geometry and appearance. The motion understanding taxonomy proposed—movements, activities, and actions—allows one to categorize particular approaches in terms of the prepresentations and knowledge required to interpret the imagery.

Fundamental to the taxonomy discussed are the mechanisms necessary to manipulate time. The recognition of movements require only simple linear (speed) invariance while the detection of activities employs more capable dynamic time warping methods. finally, the perception of actions, even actions with direct visual correlates, necessitates reasoning about qualitative temporal relationships.

One of the utilities of this division of problems is the ability to immediately identify which techniques might be applicable to a given task. One cannot expect a movement-focused algorithm to extend trivially to the recognition of higher-level action. For example, the temporal template method described will never perform generic shop-lifting detection unless the task can be formulated as detecting a particular movement.

At the heart of the taxonomy are the knowledge and representations required to support the necessary inferences. Computer vision has developed numerous ways of representing a cup (Euclidean solids, superquadrics, spline surfaces, particles); how many ways do we have to represent throwing a baseball? Or even getting a wicket?
